## Abstract

Dense surface blooms of toxic cyanobacteria in eutrophic lakes may lead to mass mortalities of fish and birds, and provide a serious health threat for cattle, pets, and humans. It has been argued that global warming may increase the incidence of harmful algal blooms. Here, we report on a lake experiment where intermittent artificial mixing failed to control blooms of the harmful cyanobacterium *Microcystis* during the summer of 2003, one of the hottest summers ever recorded in Europe. To understand this failure, we develop a coupled biological–physical model investigating how competition for light between buoyant cyanobacteria, diatoms, and green algae in eutrophic lakes is affected by the meteorological conditions of this extreme summer heatwave. The model consists of a phytoplankton competition model coupled to a one-dimensional hydrodynamic model, driven by meteorological data. The model predicts that high temperatures favour cyanobacteria directly, through increased growth rates. Moreover, high temperatures also increase the stability of the water column, thereby reducing vertical turbulent mixing, which shifts the competitive balance in favour of buoyant cyanobacteria. Through these direct and indirect temperature effects, in combination with reduced wind speed and reduced cloudiness, summer heatwaves boost the development of harmful cyanobacterial blooms. These findings warn that climate change is likely to yield an increased threat of harmful cyanobacteria in eutrophic freshwater ecosystems.

## Introduction

The summer of 2003 was probably the hottest summer in Europe of the past 500 years (Levinson & Waple, 2004; Luterbacher *et al.*, 2004). Temperature extremes were locally 5 °C higher than on average (Beniston, 2004). Climate models indicate that the summer heat-

wave of 2003 might offer a glimpse of summers to be expected in Europe in the later part of this century, as a result of global warming (Beniston, 2004; Schär *et al.*, 2004; Stott *et al.*, 2004). During this hot summer, we ran a large-scale lake experiment to control surface blooms of the harmful cyanobacterium *Microcystis*.

*Microcystis* is a cosmopolitan cyanobacterium of eutrophic freshwaters (Reynolds *et al.*, 1981; Zohary *et al.*, 1996; Chen *et al.*, 2003; Verspagen *et al.*, 2006). Cells of *Microcystis* and several other cyanobacteria contain gas vesicles (Walsby, 1994), providing them with buoyancy. These buoyant cyanobacteria float upwards during weak vertical mixing, and can form dense blooms at the water surface (Zohary & Robarts, 1990; Visser *et al.*, 1996a). Moreover, *Microcystis* can produce microcystins, a family of toxins damaging the liver of birds and

mammals, including humans. Hence, *Microcystis* blooms provide a serious threat for water quality (Chorus & Bartram, 1999; Codd *et al.*, 1999; Carmichael, 2001; Huisman *et al.*, 2005). Previous studies have indicated that warm summers with little vertical mixing provide ideal conditions for surface blooms of harmful cyanobacteria (Reynolds, 1997; Ibelings *et al.*, 2003; Robson & Hamilton, 2003; Mooij *et al.*, 2005). However, the lack of large-scale lake experiments and detailed mechanistic models has thus far limited rigorous predictions on the impact of weather conditions on cyanobacterial blooms.

Changes in vertical mixing may shift the competitive balance between buoyant cyanobacteria and sinking phytoplankton species (Walsby *et al.*, 1997; Huisman *et al.*, 2004). In this paper, we report on Lake Nieuwe Meer, a hypertrophic lake in the Netherlands, where artificial mixing successfully controls *Microcystis* blooms since 1993 (Visser *et al.*, 1996a; Huisman *et al.*, 2004). The entire lake is vertically mixed throughout summer by air bubbling. Artificial mixing led to major changes in phytoplankton species composition. Surface blooms of *Microcystis* dominating the lake before 1993 were replaced by a mixture of green algae and diatoms. Artificial mixing of Lake Nieuwe Meer is accompanied by an extensive monitoring program. Phytoplankton and nutrients are sampled frequently. Temperature loggers are moored in the lake to obtain online temperature records. A microstructure profiler is employed to monitor vertical mixing (Sharples *et al.*, 2001; Huisman *et al.*, 2004). We complemented the monitoring program by a model study of competition between buoyant cyanobacteria and sinking phytoplankton species. We coupled this phytoplankton competition model (Huisman *et al.*, 1999a, 2004, 2006; Klausmeier & Litchman, 2001) to a one-dimensional hydrodynamic model (Rodi, 1993; Mohammadi & Pironneau, 1994; Jöhnk & Umlauf, 2001; Hutter & Jöhnk, 2004). The coupled biological–physical model is driven by meteorological fields such as irradiance, wind speed, and air temperature.

During the summer of 2003, we aimed to test a new mixing regime in Lake Nieuwe Meer. We implemented a scheme in which artificial mixing was switched on and off with a 1- or 2-week periodicity, to reduce the energy costs of artificial mixing without inducing surface blooms of harmful cyanobacteria. However, when we launched this research program, we were not aware that the summer of 2003 would become the hottest summer ever recorded in Europe. In August, at the peak of the summer heatwave, there were almost instant outbursts of *Microcystis* as soon as artificial mixing was switched off. In this paper, we report on the failure of intermittent mixing to suppress *Microcystis* blooms in

Lake Nieuwe Meer. We take advantage of our coupled biological–physical model to unravel which mechanisms promoted the development of surface blooms of these harmful cyanobacteria during the summer heatwave of 2003.

## Lake experiment

Lake Nieuwe Meer is a recreational lake in the city of Amsterdam, with a surface area of 1.3 km<sup>2</sup>, a mean depth of 18 m, and a maximum depth of 30 m. The lake is connected to the canals of Amsterdam at one side and to a canal leading through the agricultural areas of the Haarlemmermeer Polder on the other side. The lake has very high nutrient concentrations (Table 1). Mean summer concentrations of total nitrogen in the epilimnion were up to 3800 µg N L<sup>-1</sup> in the late 1980s, and gradually declined to 2400 µg N L<sup>-1</sup> in 2006. Summer concentrations of total phosphorus amounted to 450 µg P L<sup>-1</sup> in the late 1980s, and gradually declined to 260 µg P L<sup>-1</sup> in 2006. Dissolved inorganic nitrogen and soluble reactive phosphorus were never depleted to limiting values (Table 1; compare with Sas, 1989; Wetzel, 2001). Summer concentrations of silica usually ranged from 700 to 3000 µg Si L<sup>-1</sup>, with a lower concentration of 100 µg Si L<sup>-1</sup> in August 1984. Accordingly, Lake Nieuwe Meer can be classified as a hypertrophic lake, where nutrient limitation of phytoplankton growth is negligible.

Dense surface blooms of the buoyant cyanobacterium *Microcystis aeruginosa* dominated the lake during summer for many years. In 1993, Water Board Rijnland installed a system of seven perforated air tubes just above the lake sediment to start artificial mixing of the lake by means of air bubbling. Artificial mixing led to major changes in phytoplankton species composition (Visser *et al.*, 1996a; Huisman *et al.*, 2004). *Microcystis* was replaced by a mixture of diatoms and large green

**Table 1** Summer nutrient concentrations (in µg L<sup>-1</sup>) in Lake Nieuwe Meer, measured monthly at 0.5 m depth in May–August

Nutrient	Mean	SD	Minimum	Maximum
Total nitrogen	3595	920	1800	6450
Dissolved inorganic nitrogen	2255	762	380	4100
Total phosphorus	406	130	200	740
Soluble reactive phosphorus	343	109	130	610
Silicate	1532	1268	100	4000

Data show the mean, SD, minimum concentration and maximum concentration measured over the years 1980–2006.

algae. The diatoms that became dominant by artificial mixing of Lake Nieuwe Meer consisted mainly of *Cyclotella* and *Stephanodiscus* species. The green algae that flourished with artificial mixing were dominated by *Scenedesmus* species, with smaller amounts of *Monoraphidium*, *Kirchneriella*, and *Dictyosphaerium*. Also, small flagellates (mainly *Cryptomonas* spp.) have become more abundant after artificial mixing was installed in the lake.

#### Mixing experiment

Artificial mixing of an entire lake requires quite some energy, and is, therefore, rather expensive. To reduce the costs, we therefore proposed an intermittent mixing regime, in which artificial mixing was alternately switched on and off for periods of 14 days during the summer of 2003. Artificial mixing of the lake was always off in winter. Artificial mixing was switched on at the end of April 2003. The intermittent mixing regime started on June 17, when artificial mixing was switched off for 2 weeks. This period was followed by only 1 week of artificial mixing (July 2–9), due to a failure in the air bubbling system. After this, the mixing was switched off for a period of 2 weeks (July 10–24), and subsequently switched on again for 2 weeks (July 25–August 7). The next mixing-off period, in the second week of August, was in phase with the peak of the extreme heatwave across Europe. Within a few days, *Microcystis* rapidly increased. Although *Microcystis* concentrations were still far below those experienced during years without artificial mixing, the Water Board decided to switch mixing on permanently from August 14 onwards, thus suppressing the unexpected *Microcystis* bloom. The measurements ended on August 26.

#### Temperature structure

The temperature structure of the lake was monitored using a permanently moored vertical array of six temperature loggers (8-bit Minilog; VEMCO, Shad Bay, Nova Scotia, Canada), placed equidistantly from the water surface to 20 m deep with a spacing of 4 m. The vertical array was mounted to a buoy near the middle of the lake. The temperature loggers recorded the temperature every 5 min over a period of 3 months, including the full experimental period.

#### Turbulence structure

The vertical turbulence structure can be derived from detailed profiles of the temperature microstructure (Imberger & Ivey, 1991; Kocsis *et al.*, 1999; Sharples *et al.*, 2001). We employed a Self-Contained Autonomous

MicroProfiler (SCAMP; Precision Measurement Engineering Inc., Carlsbad, CA, USA) to measure high-resolution profiles of temperature, pressure (depth), irradiance, chlorophyll fluorescence and conductivity (Stevens *et al.*, 1999). The free-falling SCAMP was calibrated to sink downwards at a constant velocity of  $\sim 10 \text{ cm s}^{-1}$ , collecting data at a frequency of 100 Hz. This yields a vertical resolution of  $\sim 1 \text{ mm}$ . SCAMP profiles were run at three sampling stations in the lake, on 16 sampling days spread over the experimental season. At each sampling station, we took 10 consecutive SCAMP profiles within  $\sim 80 \text{ min}$  to capture the variable nature of turbulent mixing. Turbulent dissipation rates and vertical turbulent diffusivities were calculated from the high-resolution temperature profiles according to Sharples *et al.* (2001).

#### Phytoplankton development

Water samples were taken from 1 m and 8 m depth at three sampling stations in the lake, on 17 days spread over the experimental season. The samples were fixed with Lugol's Iodine. Phytoplankton cells were counted microscopically using a Sedgewick-Rafter counting chamber and identified to the species level. Population abundances of the phytoplankton species, including colonial species like *Microcystis*, were expressed as number of cells per unit volume.

#### Model study

Complementary to the lake experiment, we developed a model to predict changes in temperature structure, turbulence structure, and phytoplankton population dynamics. The model consists of a one-dimensional hydrodynamic model coupled to a one-dimensional phytoplankton competition model. This coupled biological-physical model is forced by meteorological conditions, thus enabling model studies of different climate scenarios.

#### Hydrodynamic model

Simulations of temperature and turbulent diffusivity are based on a one-dimensional  $k-\epsilon$  turbulence model (Rodi, 1993; Mohammadi & Pironneau, 1994; Jöhnk & Umlauf, 2001; Hutter & Jöhnk, 2004). Because Lake Nieuwe Meer is a relatively small lake, the Coriolis effect is insignificant and pressure gradients generated by internal seiching can be neglected. The turbulence model is based on a system of five partial differential equations, describing the dynamics of momentum, heat, turbulent kinetic energy, and turbulent dissipation rate, respectively. The depth of the lake is indicated by the

variable  $z$ , where  $z$  runs from 0 at the surface to a maximum depth  $z_m$  at the bottom of the lake. The bathymetry of the lake is implicitly taken into account via the area–depth relation,  $A(z)$ .

Horizontal momentum related to the horizontal velocity vector,  $\mathbf{u}$ , is driven by wind stress at the surface, and vertically distributed by diffusion. The change in horizontal momentum can be described by a system of two partial differential equations (for momentum in the  $x$  and  $y$  direction, respectively)

$$\frac{\partial \mathbf{u}}{\partial t} = \frac{\partial}{\partial z} \left( (D_m + D_z) \frac{\partial \mathbf{u}}{\partial z} \right) + c_b \mathbf{u} \left| \frac{1}{A} \frac{\partial A}{\partial z} \right|, \quad (1)$$

where  $D_m$  is the molecular diffusivity of momentum for water and  $D_z$  is the vertical turbulent diffusivity which is space- and time-dependent. The second term on the right-hand side describes the loss of momentum at each depth induced by the lake's boundaries. This boundary stress term is formulated as a sliding law with a drag coefficient  $c_b$ , chosen according to the lake's settings. The two boundary conditions for the momentum equation are the continuity of shear stress at the surface generated by wind stress, with a velocity-dependent drag coefficient, and vanishing shear stress at the deepest point of the lake (Hutter, 1993).

Heat is produced by the absorption of short-wave radiation (400–3000 nm),  $E(z, t)$ , and vertically distributed by diffusion. Accordingly, dynamic changes in temperature,  $T$ , can be described as

$$\frac{\partial T}{\partial t} = \frac{1}{A} \frac{\partial}{\partial z} \left( A \left( D_h + \frac{D_z}{\sigma_h} \right) \frac{\partial T}{\partial z} \right) - \frac{1}{\rho(T)c(T)} \frac{\partial E}{\partial z}, \quad (2)$$

where  $D_h$  is the molecular diffusivity of heat in water, and  $D_z/\sigma_h$  is the turbulent diffusivity of heat expressed as the turbulent diffusivity of momentum divided by the Prandtl-number for heat,  $\sigma_h$ . The Prandtl-number is parameterized as a function of turbulent kinetic energy, turbulent dissipation rate, and temperature gradient. The bathymetry of the lake is implicitly incorporated via the area–depth relation,  $A(z)$ , in such a way that heat is conserved and radiation reaching the lake bottom is absorbed by the sediment. We neglect heat exchange between the water column and sediments, which is a common assumption for deep lakes (unless the water is heated from below by geothermal activity; e.g. Imboden & Wüest, 1995). The second term on the right-hand side describes the absorption of short-wave radiation, where  $\rho(T)$  is the density of water and  $c(T)$  is the specific heat of water, with both being functions of temperature (Chen & Millero, 1986). Short-wave radiation in the water column depends on the incident radiation at the water surface,

and decreases exponentially with depth according to Lambert–Beer's law. The two boundary conditions for the heat equation are the continuity of heat flux at the surface, driven by meteorological conditions, and a vanishing heat flux at the deepest point of the lake (Henderson-Sellers, 1984; Hutter & Jöhnk, 2004).

The dynamical distributions of turbulent kinetic energy,  $k$ , and turbulent dissipation rate,  $\varepsilon$ , are described by the two equations (Jones & Launder, 1972; Rodi, 1993; Mohammadi & Pironneau, 1994; Hutter & Jöhnk, 2004):

$$\frac{\partial k}{\partial t} = \frac{\partial}{\partial z} \left( \left( D_m + \frac{D_z}{\sigma_k} \right) \frac{\partial k}{\partial z} \right) + P + G - \varepsilon \quad (3)$$

$$\frac{\partial \varepsilon}{\partial t} = \frac{\partial}{\partial z} \left( \left( D_m + \frac{D_z}{\sigma_\varepsilon} \right) \frac{\partial \varepsilon}{\partial z} \right) + (c_{1\varepsilon}P + c_{3\varepsilon}G - c_{2\varepsilon}\varepsilon) \frac{\varepsilon}{k},$$

where  $P$  and  $G$  describe the production and loss of turbulent kinetic energy induced by shearing of the flow and buoyancy, respectively. Furthermore,  $\sigma_k$  and  $\sigma_\varepsilon$  are the Prandtl-numbers for turbulent kinetic energy and turbulent dissipation rate, both assumed to be constant, and  $c_{1\varepsilon}$ ,  $c_{2\varepsilon}$  and  $c_{3\varepsilon}$  are constants. Production and loss of turbulent kinetic energy are functions of the velocity gradient and the temperature gradient, respectively,

$$P = D_z \left| \frac{\partial \mathbf{u}}{\partial z} \right|^2, \quad G = \theta(T)g \frac{D_z}{\sigma_h} \frac{\partial T}{\partial z}, \quad (4)$$

where  $\theta(T)$  is the temperature-dependent thermal expansion coefficient of water, and  $g = 9.81 \text{ m s}^{-2}$  is the Earth's gravitational acceleration. At the boundaries, the turbulent fields are determined by heat and momentum fluxes at the interface (Wilcox, 1993), extended for buoyant fluids (Svensson, 1978). The constants and the Prandtl-numbers of the  $k$ – $\varepsilon$  turbulence model take their usual values (Launder & Spalding, 1974; Rodi, 1993; Mohammadi & Pironneau, 1994; Hutter & Jöhnk, 2004).

Finally, the vertical profile of turbulent diffusivity when artificial mixing is switched off is calculated from the relation

$$D_z = c_\mu \frac{k^2}{\varepsilon}, \quad (5)$$

where the constant of proportionality,  $c_\mu$ , takes the usual value of 0.09 (Rodi, 1993; Mohammadi & Pironneau, 1994; Hutter & Jöhnk, 2004). When artificial mixing is switched on, the turbulent diffusivity is much higher. Based on SCAMP measurements in 2003, we estimated that artificial mixing contributed a background turbulent diffusivity of  $\sim 1.6 \times 10^{-3} \text{ m}^2 \text{ s}^{-1}$ . This value is added to Eqn (5) when artificial mixing is on.

The full set of equations was integrated in time using an implicit method on an equidistant space–time grid with a spatial resolution of 0.1 m and a time resolution of 4 min. Initial values of the hydrodynamic model were a homogeneous temperature of 4 °C and zero values for all other profiles on 1 January. For each simulation, the hydrodynamic model was run over 3 years of meteorological forcing to equilibrate the hydrodynamics with the prevailing climate conditions. Only the last year of each run was coupled to the phytoplankton competition model.

### Phytoplankton model

Simulations of the phytoplankton are based on a one-dimensional phytoplankton competition model developed by Huisman and co-workers (Huisman *et al.*, 1999a,b, 2004, 2006). We consider a vertical water column with a total number of  $n$  different phytoplankton species. Because Lake Nieuwe Meer is a hypertrophic lake with very high nutrient concentrations (Table 1), the model assumes that nutrient limitation of the phytoplankton does not play a role. The population dynamics of the phytoplankton species are driven by light availability, temperature, and mixing processes.

More precisely, let  $N_i(z,t)$  denote the population density of phytoplankton species  $i$  at depth  $z$  and time  $t$ , let  $I(z,t)$  denote the local light intensity in the PAR range (400–700 nm), and let  $T(z,t)$  denote the local temperature (in °C). The population dynamics of the phytoplankton species are described by a system of reaction–advection–diffusion equations (Huisman *et al.*, 2004, 2006):

$$\frac{\partial N_i}{\partial t} = \mu_i(I, T)N_i - m_i(T)N_i + \frac{\partial}{\partial z}(v_i(T)N_i) + \frac{\partial}{\partial z}\left(D_z \frac{\partial N_i}{\partial z}\right) \quad i = 1, \dots, n. \quad (6)$$

Here,  $\mu_i(I, T)$  is the specific growth rate of species  $i$  as a function of light intensity and temperature. The term  $m_i(T)$  is the specific loss rate of species  $i$  as a function of temperature, and includes losses due to natural mortality, zooplankton grazing, and virus attack. Furthermore,  $v_i(T)$  is the vertical velocity of species  $i$  (with  $v_i > 0$  for buoyant species, and  $v_i < 0$  for sinking species), which depends on the viscosity of the water and, thereby, on temperature. Finally,  $D_z$  is the vertical turbulent diffusivity, which is space- and time-dependent. Zero-flux boundary conditions at the top and the bottom of the water column assure that the phytoplankton species neither enter nor leave the water column.

The underwater light conditions may change. For instance, the water column will become more turbid with increasing phytoplankton population densities. More specifically, according to Lambert–Beer’s law, the underwater light gradient can be described as (Huisman & Sommeijer, 2002; Huisman *et al.*, 2004):

$$I(z, t) = I_{in}(t)(1 - r) \exp\left(-\int_0^z \left[\sum_{i=1}^n \kappa_i N_i(\sigma, t)\right] d\sigma - K_{bg}z\right), \quad (7)$$

where  $I_{in}(t)$  is the incident light intensity (PAR) at the water surface,  $r$  is a reflection coefficient to correct for reflection losses at the water surface,  $\kappa_i$  is the specific light attenuation coefficient of phytoplankton species  $i$ ,  $K_{bg}$  is the background attenuation coefficient caused by all nonphytoplankton components in the water column, and  $\sigma$  is an integration variable accounting for the non-uniform phytoplankton population density distributions.

The model assumes that the specific growth rate is an increasing saturating function of light intensity, as described by a simple Monod equation (Huisman *et al.*, 1999a; Passarge *et al.*, 2006):

$$\mu_i(I, T) = \frac{\mu_{\max,i}(T)I}{\mu_{\max,i}(T)/\alpha_i + I}, \quad (8)$$

where  $\mu_{\max,i}(T)$  is the maximum specific growth rate of species  $i$  at light-saturating conditions as a function of temperature, and  $\alpha_i$  is the initial slope of the growth function under light-limited conditions. The slope  $\alpha_i$  is mainly determined by temperature-independent processes of the light reaction of photosynthesis (like light absorption), whereas  $\mu_{\max,i}$  is mainly determined by the temperature-dependent processes of the dark reaction of photosynthesis (Raven & Geider, 1988; Coles & Jones, 2000). We, therefore, assume that  $\mu_{\max,i}$  varies with temperature, while  $\alpha_i$  is independent of temperature.

The temperature dependence of the maximum specific growth rate is described by an optimum curve, which increases with temperature according to an Arrhenius-type relationship, but decreases with temperature when the temperature optimum,  $T_{opt,i}$ , is exceeded. Our functional relationship is based on Robson & Hamilton (2004), but reformulated to better describe the point of the temperature optimum:

$$\mu_{\max,i}(T) = \mu_{\max,i}(T_{opt,i}) \left[1 + b_i \left( \left( \frac{R_{1i}^{T-T_{opt,i}}}{R_{2i}^{T-T_{opt,i}}} - 1 \right) - \frac{\ln(R_{1i})}{\ln(R_{2i})} (R_{2i}^{T-T_{opt,i}} - 1) \right) \right], \quad (9)$$

where  $\mu_{\max,i}(T_{opt,i})$  is the maximum specific growth rate at the optimum temperature, and the parameters  $R_{1i}$ ,  $R_{2i}$ , and  $b_i$  describe the form of the optimum curve for

species *i*. The curve fits well to existing data of the temperature dependence of maximum specific growth rates (Reynolds, 1997; Butterwick *et al.*, 2005). We assume that the specific loss rate increases exponentially with temperature, as described by a simple  $Q_{10}$  relationship (Robarts & Zohary, 1987; Ryan, 1991):

$$m_i(T) = m_i(20)Q_i^{(T-20)/10}, \quad (10)$$

where  $m_i(20)$  is the specific loss rate at 20 °C, and  $Q_i$  describes the change in specific loss rate with a temperature change of 10 °C.

According to Stokes' Law, the vertical velocity of a nonmotile phytoplankton at low Reynolds numbers is inversely proportional to the dynamic viscosity of water (Smayda, 1970; Reynolds, 2006). Dynamic viscosity, in turn, varies with temperature (e.g. Hutter & Jöhnk, 2004). Accordingly, we modelled the temperature dependence of the vertical velocity of the different phytoplankton species as

$$v_i(T) = \frac{\eta(20)}{\eta(T)} v_i(20), \quad (11)$$

where  $\eta(T)$  is the dynamic viscosity as a function of temperature, and  $\eta(20)$  and  $v_i(20)$  are the dynamic viscosity and vertical velocity at a reference temperature of 20 °C. Because dynamic viscosity decreases with temperature, buoyant cyanobacteria will float upwards faster while sinking phytoplankton will sink faster with increasing temperature.

Numerical simulation of the phytoplankton competition model is computationally quite demanding, due to a nonlocal term in the model (i.e. the integral term in Eqn 7). A detailed presentation of our simulation techniques, with tests of the accuracy and numerical stability of the simulations, is presented in Huisman and Sommeijer (2002) and Pham Thi *et al.* (2005). The model was forced by the temperature field and turbulent diffusivity field predicted by the hydrodynamic model, and the incident light intensity (PAR, from 400 to 700 nm) measured hourly at the weather station of Schiphol airport. Simulations of the population dynamics of the phytoplankton species during the summer season were initiated with homogeneous population density distributions of the phytoplankton on the first of May.

#### Climate scenarios

Hourly values of incident radiation, air temperature, relative humidity, wind speed, and cloudiness were provided by the Royal Netherlands Meteorological Institute (KNMI) from the weather station of Schiphol airport, which is only ~5 km southwest of Lake Nieuwe Meer. These meteorological variables were used as input in the model simulations.

To investigate different climate scenarios, we chose 3 years characterized by contrasting summer temperatures, wind speeds, and cloud cover. Changes in cloud cover affect the incident radiation. This was described by a simple empirical relation (Jöhnk, 2005):

$$I_{in} = (1 - 0.65C^2)I_{sol}, \quad (12)$$

where  $C$  is cloud cover ( $0 < C < 1$ ) and  $I_{sol}$  is the solar radiation for a clear sky. According to long-term meteorological measurements of the Royal Netherlands Meteorological Institute (KNMI) in De Bilt, the Netherlands, summer air temperature increased significantly during the past century (Fig. 1a; slope =  $0.011 \pm 0.003$  °C yr<sup>-1</sup>,  $P < 0.0002$ ). Summer values of wind speed and cloudiness showed no significant trend (Fig. 1b and c). The selected years were 1956, 1991, and 2003 (Fig. 1). The summer of 1956 can be regarded as a cold summer, with high wind speeds and large cloudiness. In 1991, summer temperatures, wind speeds, and cloud cover had average values. The summer of 2003, which may reflect a glimpse of climate change to come (Beniston, 2004; Schär *et al.*, 2004; Stott *et al.*, 2004), was extremely hot with little cloud cover and low wind speeds.

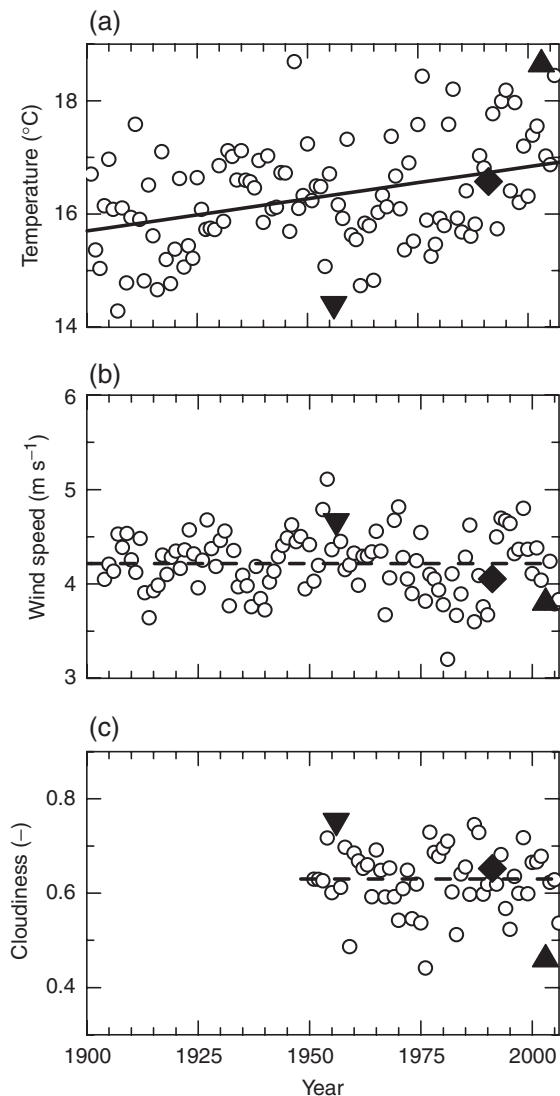

#### Model calibration

During the years 1990 and 1991 artificial mixing was not yet applied to the lake. We used the meteorological data, temperature structure, and phytoplankton development monitored during these 2 years to calibrate the hydrodynamic model and the phytoplankton model.

#### Hydrodynamic model

Wind speed and the drag coefficient in the momentum equation (Eqn 1) were the only parameters that were tuned to calibrate the hydrodynamic model. All other model parameters took standard values for lakes typical of the temperate region (Table 2). Simulations yielded the best fit when the wind speed measured at Schiphol airport was scaled by a factor of 0.92. That is, only a slight reduction of wind speed by 8% was required to calibrate the hydrodynamic model, most likely due to differences in fetch or terrain roughness between Schiphol airport and Lake Nieuwe Meer. The drag coefficient in the momentum equation was adjusted to fit the stratification behaviour of the lake. The seasonal development of the temperature stratification predicted by the calibrated model was in good agreement with the observed temperature stratification (Fig. 2a).

The incident radiation followed the ambient day-night cycle, based on hourly measurements at the

**Fig. 1** Summer weather conditions measured at De Bilt, the Netherlands, during the past century. (a) Summer air temperature. (b) Summer wind speed. (c) Summer cloud cover. Open circles show the average values over the months June, July, and August of each year. Solid line in (a) shows the significant trend line for air temperature. Dashed lines in (b) and (c) show the long-term means for wind speed and cloud cover. Additional symbols represent selected years, a very cold summer (1956; inverted triangle), an average summer (1991; diamond), and a very hot summer (2003; triangle).

weather station of Schiphol airport. Incident light is partially reflected at the water surface. This process was accounted for by a mean reflectivity of  $r = 0.06$ . The background attenuation coefficient for the underwater light field (Eqn 7) was calibrated, yielding a value of  $K_{bg} = 0.7 \text{ m}^{-1}$ . This is close to measured values of  $K_{bg} = 0.6 \text{ m}^{-1}$  in Lake Nieuwe Meer (Huisman *et al.*, 2004).

#### Phytoplankton model

We applied the model to study competition of the harmful cyanobacterium *Microcystis* against diatoms and green algae in Lake Nieuwe Meer. Parameter values and their sources are listed in Table 3.

The temperature dependence of the maximum specific growth rate, described by Eqn 9, was fitted to laboratory measurements of *Microcystis* (Reynolds, 1997). This yielded an excellent fit (Fig. 2b, blue line;  $R^2 = 0.99$ ,  $N = 6$ ). The general shape of the temperature-dependent growth rate of the diatoms was fitted to laboratory measurements of the freshwater diatom *Asterionella* (Butterwick *et al.*, 2005). Because Lake Nieuwe Meer also hosts several other diatom species (especially *Stephanodiscus* and *Cyclotella* spp.), we calibrated the height of this temperature response curve [i.e. the parameter  $\mu_{\max,i}(T_{\text{opt},i})$ ] against the seasonal phytoplankton data of 1990 and 1991. The model calibration yielded a very good correspondence with the laboratory data of *Asterionella* (Fig. 2b, compare red symbols and red line). The literature did not provide suitable data on the temperature-dependent growth rates of green algae representative for Lake Nieuwe Meer. Therefore, the temperature dependence of the green algae was fully calibrated against the seasonal phytoplankton data of 1990 and 1991. This yielded a quite plausible temperature response curve (Fig. 2b, green line). Comparison of the three temperature response curves shows that *Microcystis* has a lower maximum specific growth rate than the diatoms and green algae at temperatures below  $23^\circ\text{C}$ . However, the specific growth rate of *Microcystis* shows a stronger increase with temperature and higher optimum temperature than the diatoms and green algae (Fig. 2b). This makes *Microcystis* a relatively weak competitor at low temperatures, but a strong competitor at high temperatures.

The specific loss rate of *Microcystis*, described by Eqn 10, was adopted from Robson & Hamilton (2004). Grazing losses were probably low for *Microcystis*, due to its large colony size, toxin production, and mucilaginous envelope (DeMott, 1999; Rohrlack *et al.*, 1999; Ghadouani *et al.*, 2003), but might be more substantial for the diatoms and green algae. We lack detailed zooplankton counts for Lake Nieuwe Meer, however. Therefore, the specific loss rates of the diatoms and green algae were estimated by calibration of the model against the seasonal phytoplankton data of 1990 and 1991.

The flotation velocity of *Microcystis* was adopted from Huisman *et al.* (2004). The sinking velocities of the diatoms and green algae were estimated by model calibration, and the values thus obtained (Table 3) were of similar magnitude as the measured sinking velocities of diatoms and green algae isolated from Lake Nieuwe

Meer (Visser *et al.*, 1996b). The temperature dependence of the dynamic viscosity of water was taken from the literature (Hutter & Jöhnk, 2004). Because *Microcystis* can float upwards, whereas the diatoms and to a lesser extent also the green algae sink downwards, *Microcystis* may gain a competitive edge during periods with weak vertical mixing (Visser *et al.*, 1996a; Huisman *et al.*, 2004).

The population dynamics of the phytoplankton species predicted by the calibrated model were in good agreement with the observed population dynamics of *Microcystis* and the diatoms and green algae in Lake Nieuwe Meer (Fig. 2c and d). As predicted, the cell concentrations of *Microcystis* during August and September were two orders of magnitude higher than the cell concentrations of the diatoms and green algae when the lake was not artificially mixed. The full model, calibrated on the basis of the years 1990 and 1991, was used to predict the temperature structure, turbulence structure, and phytoplankton development in 2003.

## Results

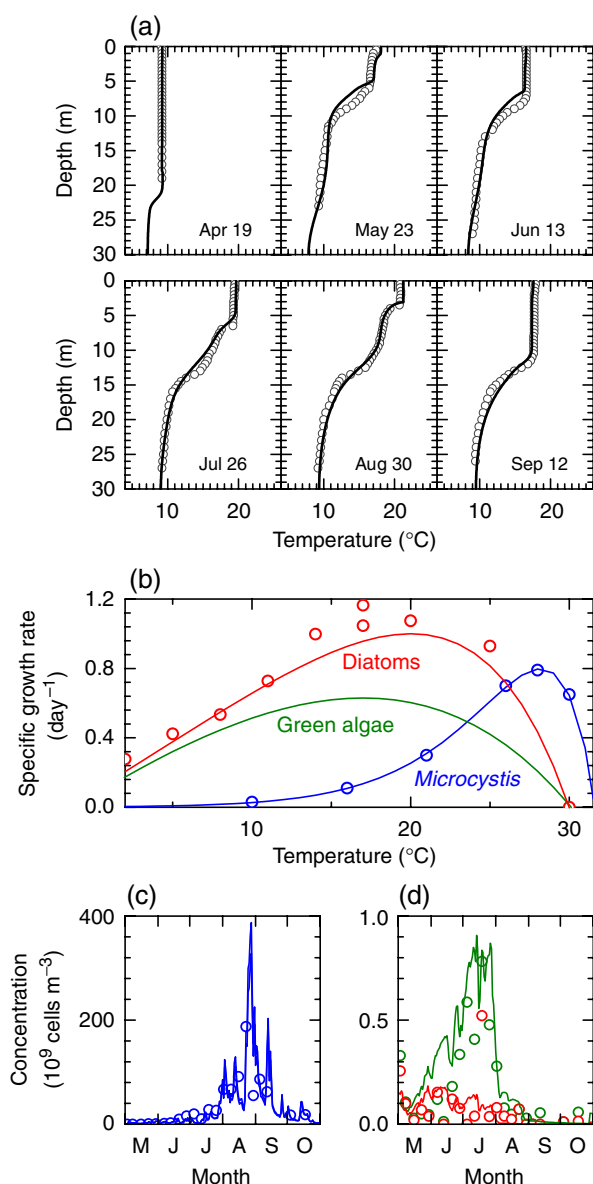

### Lake experiment

The intermittent mixing regime imposed by artificial mixing (Fig. 3a) had a major impact on the turbulence

structure, temperature structure, and phytoplankton development in 2003. Vertical turbulent diffusivity was, on average,  $\sim 3$  orders of magnitude higher with artificial mixing than without artificial mixing (Fig. 3b). When artificial mixing was switched off, the lake stratified in  $\sim 7$  days with a thermocline at  $\sim 5$  m depth (Fig. 3c). In mid-August, when air temperatures soared high at  $\sim 35^\circ\text{C}$ , lake temperature reacted even faster and a strong temperature stratification built up within 2–4 days. The water temperature near the surface increased up to a maximum of  $24^\circ\text{C}$  in mid-August (Fig. 3d). Switching on the artificial mixing typically resulted in a temporary drop in the near-surface temperature, due to mixing of warm surface water with colder water from below. The stratification generally disappeared within a few days.

During artificial mixing, the *Microcystis* population was efficiently suppressed (Fig. 3e). However, when artificial mixing was switched off for the second time, in mid-July, the *Microcystis* population increased. The increase of *Microcystis* was even stronger during the next period without artificial mixing. In mid-August, at the peak of the summer heatwave, an almost instant outburst of *Microcystis* appeared as soon as artificial mixing was switched off (Fig. 3e). Subsequently, the Water Board responsible for the water quality of the

(b) Effect of temperature on the maximum specific growth rates of *Microcystis* (blue line), diatoms (red line), and green algae (green line) representative for Lake Nieuwe Meer. Data points of *Microcystis* are from Reynolds (1997); data points of the diatoms are from laboratory measurements of *Asterionella* (Butterwick *et al.*, 2005). The temperature dependence of the green algae was estimated by model calibration against the seasonal phytoplankton data of 1990 and 1991. (c) Population dynamics of *Microcystis*, diatoms, and green algae near the water surface (0–1 m) of Lake Nieuwe Meer during the summer of 1990. Symbols represent measured data, solid lines represent model predictions.

lake decided to switch artificial mixing on permanently, thus suppressing the harmful cyanobacterium *Microcystis* during the rest of the season.

Diatoms and green algae showed a weaker response to the intermittent mixing regime. The green algae showed little variability (Fig. 3f, green symbols and line). The diatoms increased slightly during the first and second mixing-off period (Fig. 3f, red symbols and line), when the water temperature was near their optimum temperature (Fig. 2b). During the third mixing-off period, in mid-August, the diatom concentration dropped, most likely due to high water temperatures exceeding their temperature optimum combined with rapid sedimentation caused by reduced turbulent mixing. As a result, during the third mixing-off period, *Microcystis* reached 50 times higher cell concentrations at the surface than the diatoms and green algae.

During the mixing-off periods, *Microcystis* reached 30–50 times higher concentrations near the water surface than at 8 m depth. This indicates that many *Microcystis* cells floated upwards when mixing was off. For comparison, diatoms and green algae reached at most ~4 times higher concentrations near the water surface than at 8 m depth during mixing-off periods. When artificial mixing was switched on, the phytoplankton concentrations were always very similar at 1 and 8 m depth, indicating that artificial mixing resulted in effective vertical homogenization of *Microcystis* and all other phytoplankton populations.

#### Model simulation of the lake experiment

Model predictions of the hydrodynamic model were generally in very good agreement with the measured turbulence structure and temperature structure of 2003. Both long-term trends and short-term fluctuations were captured by the model. An example is shown in Fig. 3d, which illustrates the excellent match between the predicted and measured temperature near the water surface. The model predictions were also largely consistent with the observed phytoplankton population dynamics. During the first mixing-off period, in June, the model predicted a small *Microcystis* peak, which was not visible in the data (Fig. 3e). This might be due to horizontal patchiness in the distribution of buoyant cyanobacteria. The increase of *Microcystis* in the second mixing-off period in July, the main outburst of *Microcystis* in the third mixing-off period in mid-August, and the rapid decline of *Microcystis* when mixing was switched on, were all captured by the model predictions (Fig. 3e). Diatoms and green algae could also be simulated fairly well (Fig. 3f).

Which species traits enabled the ecological success of *Microcystis* during the summer heatwave of 2003? To address this question, we explored model simulations in which we gave our modelled *Microcystis* different traits. For instance, we shifted the temperature

**Table 3** Species parameters used in the model simulations

Parameter	Description	<i>Microcystis</i>	Diatoms	Green algae	Units

optimum of *Microcystis* downwards, from 28 to 20 °C, to match the temperature optimum of the diatoms while keeping all other *Microcystis* parameters the same. In these model simulations, the *Microcystis* population peaked much more strongly during the second mixing-off period in mid-July when temperatures were close to 20 °C, while the *Microcystis* population remained smaller during the third mixing-off period in mid-August because the higher temperatures inhibited its growth rate. We also investigated model simulations in which the buoyancy of *Microcystis* was removed. Without its buoyancy, *Microcystis* could not float to the surface when mixing was off, and thereby lost its competitive edge in comparison with diatoms and green algae. Hence, *Microcystis* quickly disappeared. In total, these simulations show that the ecological success of *Microcystis* during summer heatwaves can be attributed to its positive buoyancy in combination with its high-temperature optimum compared with other phytoplankton. These are highly advantageous traits during stratified and warm conditions.

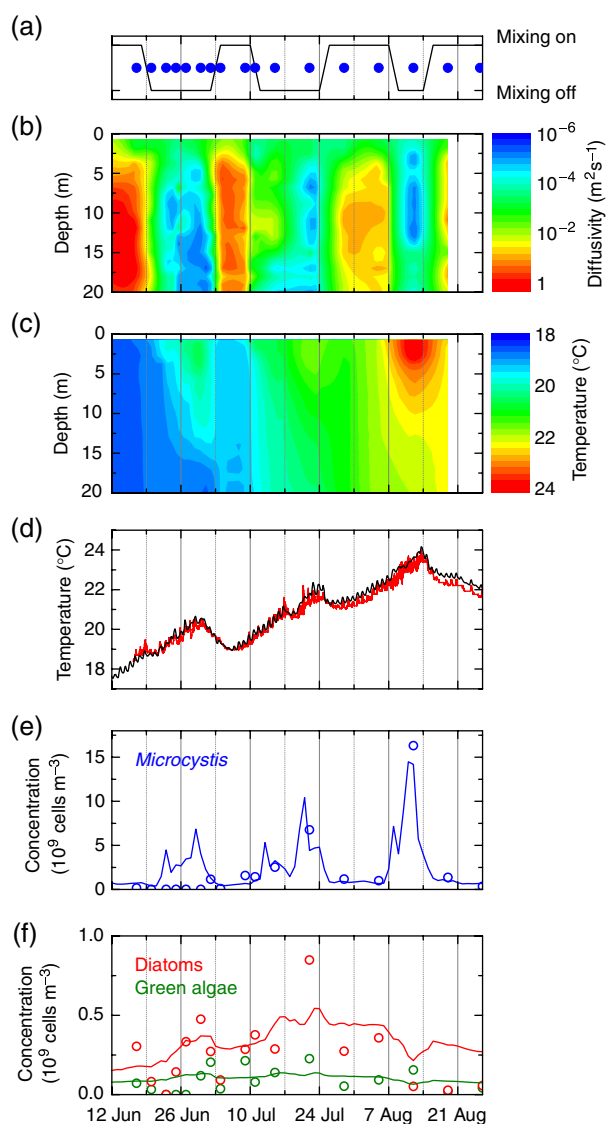

#### Model study of climate scenarios

To investigate in further detail how weather conditions during the summer season (May–October) would affect the development of harmful cyanobacteria, we simulated the full model for three different summers: the cold summer of 1956, the average summer of 1991, and the exceptionally hot summer of 2003. In these model simulations, artificial mixing was switched off. That is, the hydrodynamics and phytoplankton population

dynamics in the lake were solely driven by meteorological forcing.

The model predictions showed that in cold summers, like 1956, the temperature stratification in the lake was relatively weak and diatoms and green algae reached their highest concentrations at the end of June and early July (Fig. 4a). From mid-July onwards, *Microcystis* formed surface blooms, with cell concentrations reaching  $\sim 0.2 \times 10^{12} \text{ cells m}^{-3}$  in August and September. For ‘average’ meteorological conditions, as in the summer of 1991, the model predictions yielded a rather similar picture. Diatoms and green algae dominated in June and early July, while a *Microcystis* bloom developed in late summer, when lake surface temperatures and stability conditions were in favour of buoyant cyanobacteria (Fig. 4b). Storms and surface cooling associated with strong mixing suppressed the *Microcystis* bloom in September. During the exceptionally hot summer of 2003, the model predicted the development of a warm surface layer with little vertical mixing from early June onwards (Fig. 4c). This triggered high specific growth rates of *Microcystis* floating towards the surface, which resulted in dense *Microcystis* blooms with cell concentrations exceeding  $1.2 \times 10^{12} \text{ cells m}^{-3}$  at the height of the summer heatwave in mid-August (Fig. 4c). Diatoms and green algae, in contrast, suffered from the early development of a stable stratification. Their sedimentation losses exceeded their growth rates, keeping their cell concentrations at very low values from early summer onwards.

In all 3 years, the model predicted rather spiky patterns for the surface concentrations of *Microcystis* (Fig. 4, third row, solid lines). These spikes represent

**Fig. 3** Mixing experiment in Lake Nieuwe Meer during the summer heatwave of 2003. (a) Outline of the mixing experiment in Lake Nieuwe Meer. The line shows when artificial mixing was switched on and off. Dots show sampling dates for SCAMP profiles and phytoplankton. (b) Contour plot of vertical turbulent diffusivity, measured with the SCAMP profiler in downward mode (hence, the first 0.5 m could not be measured). (c) Contour plot of temperature, measured with the SCAMP profiler. (d) Temperature at 4 m depth, observed with temperature loggers (red line) and predicted by model simulations (black line). (e) Observed and simulated population densities of *Microcystis* near the water surface (0–1 m). Solid lines in (e) and (f) are model predictions, symbols represent measured data.

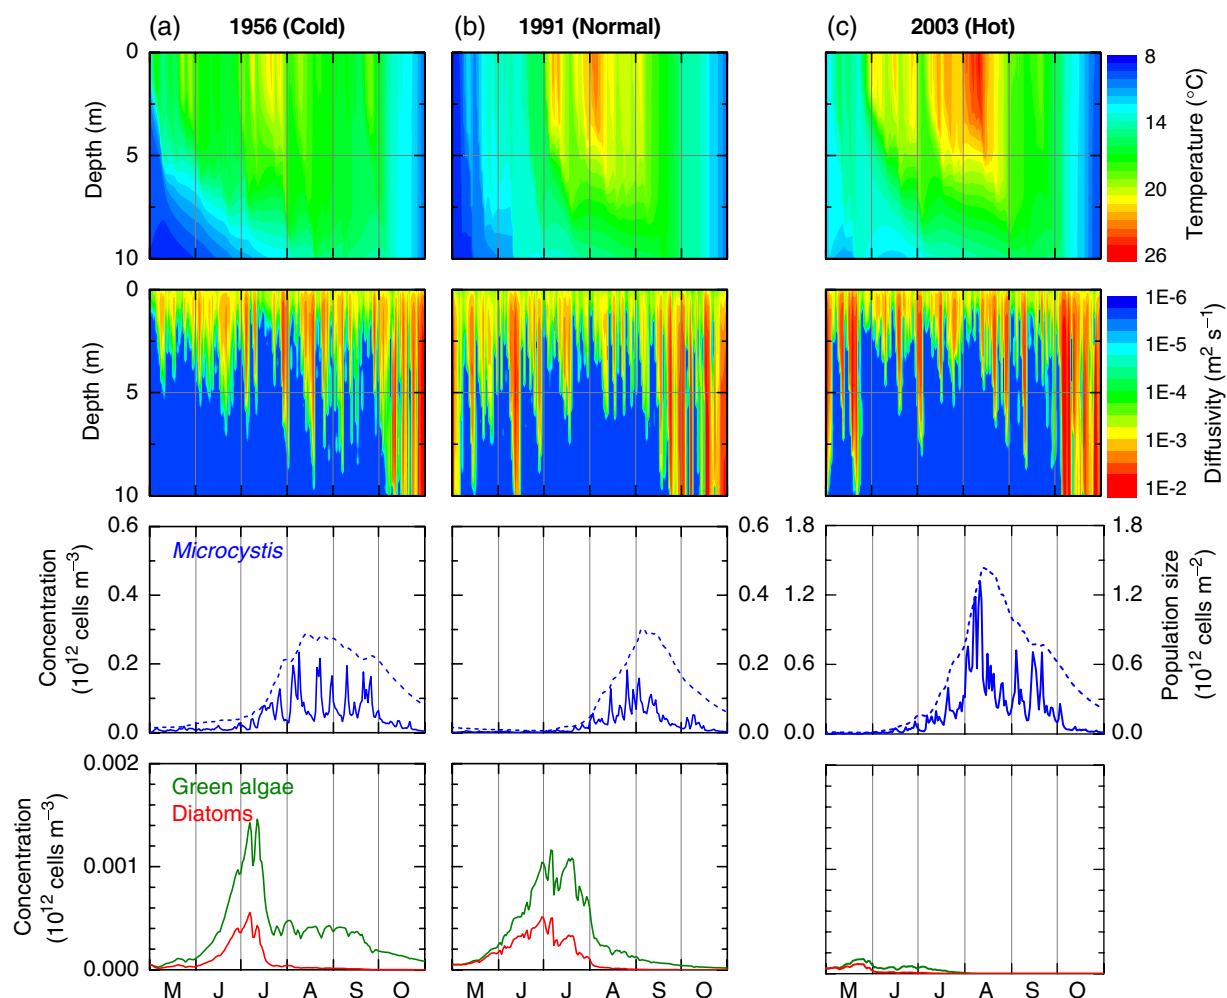

surface blooms. More precisely, when the spikes hit the smooth dashed lines in Fig. 4, the entire *Microcystis* population is concentrated in the upper meter of the

water column. Comparison with the turbulent diffusivity patterns (Fig. 4, second row) shows that surface blooms were predicted during periods with very low turbulent mixing. Suitable conditions for the development of surface blooms occurred only a few days per month, even during the summer heatwave of 2003. In contrast to the frequent ups and downs of the surface concentration, the depth-integrated population of *Microcystis* (dashed line) showed smooth seasonal changes. Hence, the model predicted that *Microcystis* populations were characterized by slow seasonal dynamics, but with frequent redistributions of the population over depth due to changes in turbulent mixing. The model further predicted that the peaks of the diatoms and green algae occurred during periods with strong vertical mixing. Interestingly, the timing of the surface blooms of *Microcystis* often coincided with little dips in the surface concentrations of the diatoms and green algae (compare the two lower panels in Fig. 4a).

#### *Impact of different meteorological factors*

The summer heatwave of 2003 was characterized not only by high temperatures but also by reduced wind speed and little cloudiness (Fig. 1). The simulations in Fig. 4 do not say which of these different meteorological factors are the key determinants of the explosion of the *Microcystis* population during the summer heatwave of 2003. Therefore, we ran a second set of model simulations to unravel how the factors temperature, wind speed, and cloudiness have contributed to the population development of *Microcystis* in 2003. For this purpose, we first simulated the full model under the assumption that 2003 would have been an average summer. That is, we transformed the meteorological data, by shifting the hourly meteorological time series of 2003 by a constant value in such a way that the summer-averaged meteorological conditions would fall exactly on the trendlines for the year 2003 (Fig. 1). We shall call this the trend year. The phytoplankton development predicted for the trend year was quite similar to the phytoplankton development simulated for the cold summer of 1956 and the average summer of 1991, with maximum surface concentrations of  $\sim 0.2 \times 10^{12}$  cells  $\text{m}^{-3}$  (Fig. 5a; compare with Fig. 4a and b).

Next, we investigated the sole effect of reduced cloudiness, by forcing the model with the cloudiness actually observed in 2003 while maintaining the wind speed and air temperature on the trend line. This showed that a decrease in cloudiness, and hence an increase in surface irradiance, led to a higher summer abundance of *Microcystis* (Fig. 5b). In a similar way, we investigated the impact of the reduced wind speed and

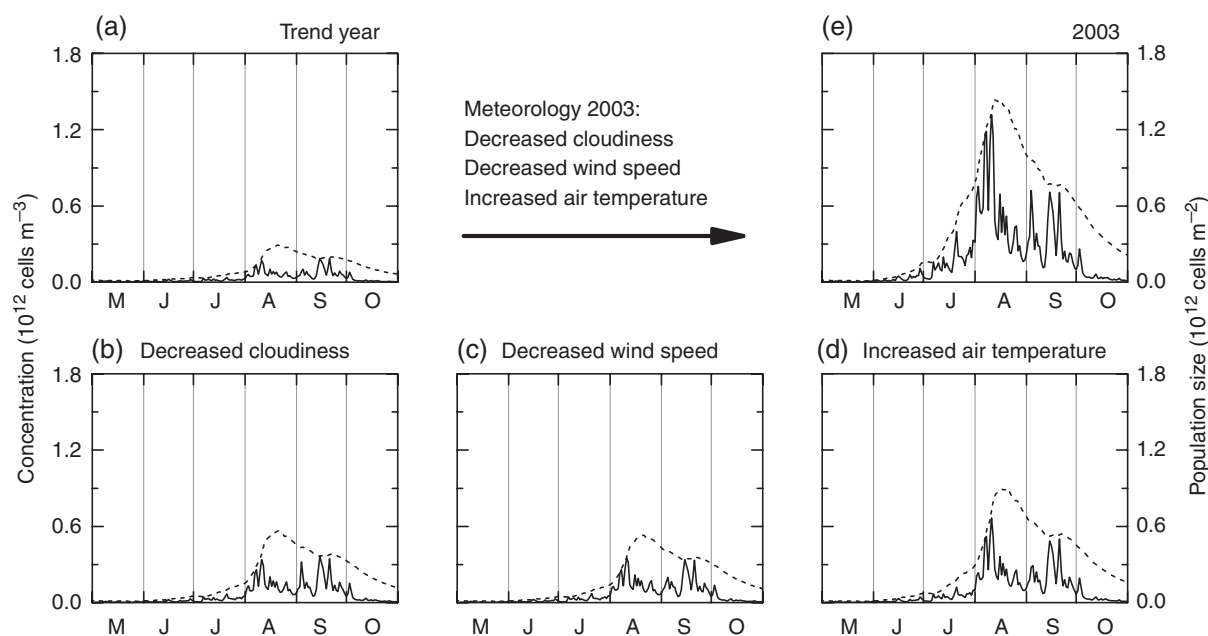

**Fig. 4** Model simulation of hydrodynamics and phytoplankton dynamics during three contrasting summers. (a) The cold summer of 1956, (b) the average summer of 1991, and, (c) the hot summer of 2003. Top panels show the temperature contour plots. The second row shows contour plots of the turbulent diffusivities. The third row shows the surface concentrations of *Microcystis* (solid lines, in cells  $\text{m}^{-3}$ ) and the depth-integrated population size of *Microcystis* (dashed lines, in cells  $\text{m}^{-2}$ ). The fourth row shows the surface concentrations of diatoms (red lines) and green algae (green lines). Note the difference in scale between the *Microcystis* concentrations (third row) and the concentrations of diatoms and green algae (fourth row).

increased air temperatures of 2003, respectively. Reduced wind speed also led to a higher summer abundance of *Microcystis* (Fig. 5c; compare with Fig. 5a). Similarly, increased air temperatures clearly yielded a higher summer abundance of *Microcystis* (Fig. 5d; compare Fig. 5a). Comparison of Fig. 5b–d shows that the summer abundance of *Microcystis* responded more strongly to the increased air temperatures of 2003 than to the reduced cloudiness and reduced wind speed of 2003.

Model simulations using the complete meteorology of 2003 revealed that the combination of reduced cloudiness, reduced wind speed, and increased air temperatures led to a considerably higher summer abundance of *Microcystis* than any of these factors in isolation (Fig.

5e; compare with Fig. 5b–d). Thus, according to the model simulations, the explosion of *Microcystis* during the exceptional summer heatwave of 2003 should not be attributed to a single meteorological factor, like temperature, but resulted from the combined effects of low cloudiness, low wind speeds, and high air temperatures.

Low wind speeds and high air temperature do not affect phytoplankton growth directly, but only indirectly, through changes in water temperature and turbulent mixing. Hence, what is the relative contribution of these different pathways to the development of *Microcystis* blooms during summer heatwaves? We addressed this question by further comparison of the model simulations using the actual meteorology of 2003 with model

**Fig. 5** Model prediction of the phytoplankton population dynamics, in response to changes in cloudiness, wind speed, and air temperature. (a) Model prediction assuming that cloudiness, wind speed, and air temperature match the values on the trendline predicted for 2003 (solid lines in Fig. 1). (b–d) Model predictions when one of these meteorological factors is represented by the actual values measured during the summer heatwave of 2003, while the other two factors match the long-term trend values. (b) Model prediction when cloudiness is reduced to the actual values measured during the summer heatwave of 2003. (c) Model prediction when wind speed is reduced to the actual values measured during the summer heatwave of 2003. (d) Model prediction when air temperature is increased to the actual values measured during the summer heatwave of 2003. (e) Model prediction when cloudiness, wind speed, and air temperature all take the actual values measured during the summer heatwave of 2003. Solid lines show the surface concentrations of *Microcystis* (in cells  $\text{m}^{-3}$ ), while dashed lines show the depth-integrated population size of *Microcystis* (in cells  $\text{m}^{-2}$ ).

simulations using the meteorological conditions calculated for the trend year. During the summer heatwave of 2003, the air temperature was  $1.8^{\circ}\text{C}$  (= 11%) higher than expected by the trend line (Figs 1a and 6). Cloudiness and wind speed in 2003 were 19% and 10% lower than expected by the trend line (Figs 1b, c and 6). According to the model simulations, this resulted in a 10% higher water temperature and a 9% lower magnitude of turbulent diffusivity during the summer heatwave of 2003 (Fig. 6). The high water temperature and low turbulent diffusivity, in turn, suppressed the population abundances of diatoms and green algae by 70–87% when compared with the trend year. These strong negative effects exceeded the positive effect of reduced cloudiness on diatoms and green algae. The increase in water temperature during the summer heatwave, by  $1.9^{\circ}\text{C}$ , had a very large positive effect on the *Microcystis* population (an increase of 385%; Fig. 6), while the low turbulent diffusivity had a smaller positive effect. Reduced cloudiness had only a minor direct effect on the *Microcystis* population. In total, the model simulations predicted that the 2003 conditions increased the *Microcystis* population by 508%, which exceeded the additive

contributions of the different pathways. This points at synergistic effects of high water temperature and low turbulent diffusivity on the development of *Microcystis* blooms during summer heatwaves.

## Discussion

Originally, this study did not intend to investigate the impact of climate change on harmful cyanobacteria. We set out to study how intermittent artificial mixing of Lake Nieuwe Meer would suppress surface blooms of *Microcystis*. However, owing to the extreme summer of 2003, we obtained a study on the response of *Microcystis* to a major summer heatwave. The combination of the lake experiment with a summer heatwave allowed us to disentangle the effect of mixing processes and weather conditions on the population development of this harmful cyanobacterium. Both the model predictions and experimental results show that, during the summer heatwave of 2003, *Microcystis* rapidly increased as soon as artificial mixing was switched off (Fig. 3).

We have aimed to develop a model that can make realistic predictions on the development of harmful

**Fig. 6** Schematic summary of the effects of summer heatwaves on phytoplankton biomass. The upper level represents the meteorological variables (air temperature, cloudiness, and wind speed). These meteorological variables affect the water temperature and turbulent diffusivity of aquatic ecosystems. Water temperature, cloudiness ('light'), and turbulent diffusivity drive the population dynamics of the phytoplankton species. For each variable, the numbers inside the boxes give the relative and absolute differences between the summer heatwave of 2003 and an average summer (where an average summer is defined by meteorological conditions that fall on the trendlines in Fig. 1). Percentages along the arrows show the relative differences between the summer heatwave of 2003 and an average summer, caused by the pathway represented by that arrow. For instance, all else being equal, high water temperatures during the summer heatwave of 2003 were responsible for a 385% increase of the *Microcystis* population compared with an average summer. In total, the *Microcystis* concentration was 508% higher during the summer heatwave of 2003 than during an average summer. Note that the percentages of different pathways do not add up, because of interactive effects between different pathways. The values are based on model simulations; the turbulent diffusivity is evaluated on a log-10 scale.

cyanobacterial blooms in relation to climate change. Yet, all models are simplifications of reality, and our model is no exception to this rule. Several aspects of reality have been simplified or ignored. For instance, the physical part of the model ignored the spectral and angular distribution of the underwater light field (Kirk, 1994), as well as the transport of phytoplankton by horizontal processes (Verhagen, 1994). The biological part of the model neglected buoyancy regulation of *Microcystis* (Visser *et al.*, 1997; Rabouille *et al.*, 2005), and lumped more than 60 phytoplankton species identified in Lake Nieuwe Meer in only three functional groups. Despite these simplifications, we are confident that the model predictions are quite robust. The model structure is firmly based on well-tested physical models (Svensson, 1978; Jöhnk & Umlauf, 2001; Peeters *et al.*, 2007a) and plankton models (Huisman *et al.*, 1999a,b, 2004; Passarge *et al.*, 2006). Parameter estimates are based on detailed measurements of physical structure

and phytoplankton physiological data (Reynolds, 1997; Huisman *et al.*, 2004; Robson & Hamilton, 2004; Butterwick *et al.*, 2005), and the model predictions show good correspondence with the available data (Figs 2 and 3).

The model simulations illustrate that the development of *Microcystis* blooms is indeed very sensitive to the weather conditions in summer (Fig. 4). During cold summers, *Microcystis* cells may float upwards during periods of weak turbulent mixing and form surface blooms (Fig. 4a). The density of these surface blooms remains limited, however, because cold summers prevent the development of a large *Microcystis* population. In contrast, hot summers boost the growth of *Microcystis* populations through a combination of different mechanisms. First, *Microcystis* has a high temperature optimum compared with most diatoms and green algae, and an exceptionally large  $Q_{10}$  value for growth compared with other phytoplankton species (Fig. 2b;

see also Reynolds, 1997; Coles & Jones, 2000; Butterwick *et al.*, 2005). Hence, the maximum specific growth rate of *Microcystis* rises steeply with increasing temperatures. Second, high temperatures promote a strong stratification of the water column, thereby suppressing vertical turbulent mixing. In eutrophic waters, reduced vertical mixing shifts competition for light in favour of buoyant cyanobacteria like *Microcystis*, which float upwards to form dense surface blooms shading other phytoplankton species (Walsby *et al.*, 1997; Huisman *et al.*, 2004). Third, high temperatures reduce the viscosity of water. All else being equal, a lower viscosity yields higher flotation velocities of buoyant species and higher sinking velocities of sinking species, which also favours the dominance of buoyant cyanobacteria over sinking diatoms and green algae. According to our model simulations, the combination of these three mechanisms leads to dense surface blooms of *Microcystis* during summer heatwaves.

The development of dense surface blooms of buoyant cyanobacteria during summer heatwaves is confirmed by other studies. August 2003 yielded more reports on surface blooms of harmful cyanobacteria in lakes in the Netherlands than ever before (Kardinaal & Visser, 2004). In the Oostvaardersplassen, one of the major bird sanctuaries in northwestern Europe, dense surface blooms of cyanobacteria were accompanied by mass mortalities of birds (especially ducks and geese). Several lakes were closed for recreation. In the southern hemisphere, an extremely dense bloom of *Microcystis* developed in the Swan River estuary, Australia, in the year 2000 (Atkins *et al.*, 2001). This coincided with a very hot summer weather, with water temperatures approaching 30 °C. Model studies showed that these exceptionally high water temperatures, in combination with unusual hydrological conditions, favoured the bloom development of *Microcystis* in the Swan River estuary (Robson & Hamilton, 2003, 2004). A recently published long-term study investigated the dominance of buoyant cyanobacteria (mainly *Microcystis*) in the Hudson River estuary, USA, in relation to physical and chemical parameters (Fernald *et al.*, 2007). Cyanobacterial dominance and abundance were both strongly correlated with summer temperature, and over 80% of the among-year variance in cyanobacterial dominance could be explained by summer temperature in a linear model. Consistent with our findings, Fernald *et al.* (2007) attributed the observed cyanobacterial dominance during warm summers by the direct effect of temperature on cyanobacterial growth rates in combination with indirect effects through enhanced stratification and reduced vertical mixing.

These results add to previous studies, which have shown that a warmer climate predicted by climate

change scenarios may shift the timing of the phytoplankton spring bloom (Edwards & Richardson, 2004; Winder & Schindler, 2004; Peeters *et al.*, 2007b), and will lead to changes in phytoplankton species composition and phytoplankton diversity (Elliott *et al.*, 2005; De Senerpont Domis *et al.*, 2007). In accordance with recent findings of Elliott *et al.* (2006), we suggest that rising temperatures may have quite contrasting effects in oligotrophic and eutrophic waters. In oligotrophic waters, nutrient limitation prevents the development of dense phytoplankton blooms. Warming of surface layers will increase vertical stratification, which suppresses the upward flux of nutrients (Bopp *et al.*, 2001; Sarmiento *et al.*, 2004). As a consequence, rising temperatures may reduce the nutrient supply to the euphotic zone, and may thus reduce and even destabilize phytoplankton growth in oligotrophic waters (Schmittner, 2005; Behrenfeld *et al.*, 2006; Huisman *et al.*, 2006). In contrast, our results for Lake Nieuwe Meer are based on hypertrophic conditions, where nutrient limitation does not play a role. If nutrients are in excess, light energy is the major factor limiting phytoplankton growth. Buoyant cyanobacteria have a major advantage in competition for light, because they can increase their own access to light while casting shade upon their competitors (Walsby *et al.*, 1997; Klausmeier & Litchman, 2001; Huisman *et al.*, 2004). Hence, the prediction that summer heatwaves promote dense surface blooms of buoyant cyanobacteria particularly applies to eutrophic and hypertrophic waters.

According to recent climate studies, the European summer heatwave of 2003 might be a prototype of future summers in the next 50–100 years (Beniston, 2004; Schär *et al.*, 2004; Stott *et al.*, 2004). These summer heatwaves are characterized by a very stable high-pressure system above northwestern Europe, generating high air temperatures, reduced wind speed, and reduced cloudiness compared with the long-term mean (Fig. 1). Our model simulations indicate that particularly high air temperatures, and also reduced wind speed and reduced cloudiness, each have the potential to promote the bloom development of *Microcystis*. The model points at the following climatic effects (Fig. 6):

- (1) High air temperatures increase the water temperature of the surface-mixed layer. As discussed above, high water temperatures increase the growth rate of *Microcystis*, suppress vertical turbulent mixing, and reduce viscosity. Thus, high air temperatures strongly favour the development of *Microcystis* blooms.
- (2) Reduced wind speed leads to a more stable stratification and a slightly shallower thermocline. This,

in turn, also has a (small) positive effect on water surface temperatures. Reduced wind speeds are thus an advantage for buoyant *Microcystis* in terms of reduced vertical mixing and slight increase in water temperature.

- (3) Reduced cloudiness, and hence sunnier conditions, slightly enhance the growth rate of buoyant cyanobacteria through an increased light availability. Furthermore, reduced cloudiness increases short-wave irradiance and decreases long-wave radiation entering the water column. In total, there is a net increase of the heat input, which leads to a slight increase in water temperature and reduced vertical mixing.

Although high air temperatures have the strongest effect on bloom development of *Microcystis*, the combination of high air temperatures with reduced wind speed and reduced cloudiness leads to an even higher summer abundance of *Microcystis* than any of these factors alone (Figs 5 and 6). This implies that studies that focus solely on changes in temperature, without taking into account wind speed and cloudiness, may seriously underestimate the impact of climate change on the bloom development of harmful cyanobacteria. This highlights the need for realistic future scenarios of wind speed and cloudiness in climate models. Whereas temperature scenarios are readily available from current climate models, there is still uncertainty in future scenarios for wind speed and cloudiness predicted by the current generation of climate models (McAvaney *et al.*, 2001; Smits *et al.*, 2005).

In conclusion, the theory and lake experiment presented in this study show that, in hypertrophic waters, summer heatwaves boost the population growth of *Microcystis* as soon as these buoyant cyanobacteria are released from vertical mixing. According to recent climate studies, the risk of European heatwaves as hot as 2003 will increase rapidly (Beniston, 2004; Schär *et al.*, 2004; Stott *et al.*, 2004). An increased threat of harmful cyanobacterial blooms thus seems a likely future scenario for eutrophic freshwater ecosystems.

## Acknowledgements

We thank the anonymous referees for their thoughtful comments, and Floris de Jongh, Linda van den Hove, and Bart Schaub for field and lab assistance. We are most grateful to Water Board Rijnland for all help with the artificial mixing experiment. Meteorological data were kindly provided by the Royal Netherlands Meteorological Institute (KNMI). P. M. V., K. D. J. and J. H. were supported by the Earth and Life Sciences Foundation (ALW), which is subsidized by the Netherlands Organization for Scientific Research (NWO). B. S. acknowledges support from the Dutch BSIK-BRICKS project.
